Keywords: Dyke intrusion; Magmatic extension; Continental rifting; Heat-flow; Thermal modelling.

Abstract

A consensus has emerged in recent years from a variety of geoscientific disciplines that extension during continental rifting is achieved only partly by plate stretching: dyke intrusion also plays an important role. Magma intrusion can accommodate extension at lower yield

26 stresses than are required to extend thick, strong, unmodified continental lithosphere
27 mechanically, thereby aiding the breakup process. Dyke intrusion is also expected to heat
28 and thereby weaken the plate, but the spatial extent of heating and the effect of different
29 rates of magmatic extension on the timescales over which heating occurs are poorly
30 understood. To address this issue, a numerical solution to the heat flow equation is
31 developed here to quantify the thermal effects of dyke intrusion on the continental crust
32 during rifting. The thermal models are benchmarked against a priori constraints on crustal
33 structure and dyke intrusion episodes in Ethiopia. Finite difference models demonstrate that
34 magmatic extension rate exerts a first order control on the crustal thermal structure. Once
35 dyke intrusion supersedes faulting and stretching as the principal extensional mechanism
36 the crust will heat and weaken rapidly (less than 1 Ma).

37 In the Main Ethiopian Rift (MER), the majority of present-day extension is focused on ~20
38 km-wide Quaternary-Recent axial magmatic segments that are mostly seismogenic to mid-
39 crustal depths and show P-wave seismic velocities characteristic of heavily intruded
40 continental crust. When reviewed in light of our models, these observations require that no
41 more than half of the MER's extension since ~2Ma has been achieved by dyke intrusion.
42 Magmatic heating and weakening of the crust would have rendered it aseismic if dyke
43 intrusion accounted for the entire 6 mm/yr extension rate. In the older, faster extending (16
44 mm/yr) Red Sea rift (RSR) in Afar, dyke intrusion is expected to have had a more dramatic
45 impact on crustal rheology. Accordingly, effective elastic plate thickness and Moho depth in
46 the Danakil region of northernmost Afar are markedly reduced and seismicity is shallower
47 than in the MER. Thermally driven variations in crustal rheology over time in response to
48 dyke intrusion thus play an important role in the development of continent-ocean transition.

49

50 1. Introduction

51 It is well established that continental rifts develop initially in a mechanical fashion, with along
52 axis segmentation governed by large-scale border faults defining early half-graben rift
53 morphology (e.g., Hayward and Ebinger 1996). A consensus is gradually emerging from a
54 number of tectonically active rifts and rifted continental margins worldwide, however, that
55 magma intrusion also plays an important role in extension prior to the onset of sea-floor
56 spreading (e.g., Maguire et al. 2006, White et al. 2008, Thybo and Nielsen 2009). This is an
57 appealing idea, since it obviates the need for large-scale tectonic forces to rupture thick,
58 strong cratonic lithosphere: dyke intrusion can occur at lower stresses than are required for
59 the stretching of thick continental lithosphere (e.g., Buck 2004, 2006, Bialas et al., 2010).
60 However, the subsequent effect of magma intrusion on the thermal structure (and by
61 inference, the strength) of the plate over time is poorly understood. It likely has important
62 implications for the thermal evolution and subsidence history of the extending plate (e.g.,
63 Thybo and Nielsen 2009), including whether or not continent-ocean transition is heralded by
64 an abrupt episode of continental plate thinning and subsidence after a period of heating and
65 weakening by protracted magma intrusion (Bastow and Keir 2011; Keir et al., 2013).

66 To address these issues, a thermal model is developed to understand better the evolution of
67 continental crust during extension by dyke intrusion. The model space is parameterised as
68 an array of cells for which the heat-flow equation is solved numerically by finite difference
69 scheme. The effects of variable magma temperature, dyke injection frequency and size, and
70 geothermal gradient on the thermal evolution of the crust over time during rifting are tested
71 by mapping the solidus and 600°C isotherm (representing the brittle-ductile transition
72 temperature) positions. In a tectonically active rift this is a testable hypothesis seismically,
73 since crustal seismicity is not expected to develop at temperatures greater than ~600°C
74 (e.g., Maggi et al., 2000a).

75 To ground-truth the thermal models and input parameters, this study draws on geoscientific
76 constraints from on-going extension in the East African (EAR) and Red Sea (RSR) rift
77 systems in Ethiopia (Figure 1). The region exposes sub-aerially several sections of

asynchronous rift sector development above a hot (e.g., Rooney et al., 2012; Ferguson et al., 2013), low wavespeed (Bastow et al., 2008) mantle; from embryonic continental rifting in the slowly (~6 mm/yr) extending Main Ethiopian rift (MER) in the south (Kogan et al., 2012), to incipient oceanic spreading in the more rapidly extending RSR and Gulf of Aden Rift in Afar (e.g., Hayward and Ebinger, 1996; McClusky et al., 2010). Real-time geodetic and seismic observations of dyke intrusion episodes (Wright et al. 2006, Keir et al. 2009, Grandin et al., 2011) are available from the region, offering considerable advantage over studies of extinct or buried rifted margins in constraining when and how dykes intrude the crust. The region is also well-understood geophysically, with detailed constraints on parameters such as crustal thickness, effective elastic plate thickness and P-wave seismic velocity structure all available (for reviews, see e.g., Bastow et al., 2011; Keir et al., 2013).

In the MER, a combination of GPS surveys and structural geology studies point towards ~80% of present-day strain being accommodated at least partly by magma intrusion within a relatively narrow (~20 km) rift-axial zone, also known as the Wonji Fault Belt (WFB: Mohr 1967, Ebinger and Casey 2001). However, precisely what proportion of extension has been accommodated by dyke intrusion into the still-thick MER crust since ~2 Ma is uncertain. In the Danakil depression, where crustal thickness is markedly thinner than elsewhere in Afar (Makris and Ginzburg 1987), it has been proposed that Pliocene-Recent basin development and voluminous Quaternary volcanism are the result of a late-stage of plate stretching following a protracted period of localised magma-intrusion (Bastow and Keir 2011, Keir et al. 2013). This study explores whether episodes of dyke intrusion during continental breakup are capable of heating the continental crust sufficiently over time for it then to behave in a ductile manner by plate stretching, prior to the development of a new mid-ocean spreading centre.

2. Mathematical Model

The thermal evolution of a vertical dyke intruded into continental crust (Figure 2) is modelled by solving the two-dimensional (2D) heat flow equation both horizontally (x -direction) and in depth (z). The model is set up in a similar manner to previous studies (Royden et al., 1980; Buck, 2004; Buck et al., 2005; Bialas et al., 2010) with a vertical cross-section through the crust incorporating a model rift axis where consecutive dykes intrude along the centre of the previous one. The dykes are intruded at a time-averaged rate which is constant at all depths (z) beneath the rift axis. Homogeneous composition continental crust is assumed, such that thermal conductivity (K), diffusivity (κ), density (ρ), specific heat capacity (C_p) and latent heat of fusion (L) remain constant as a function of depth and temperature. The 2D heat-flow equation, incorporating the latent heat of fusion is

$$\rho C_p \frac{\partial T}{\partial \tau} + \rho L \frac{\partial X}{\partial \tau} = K \nabla^2 T$$

Equation 1

where $\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial z^2}$, $T(x, z, \tau)$ is the temperature, $X(x, z, \tau)$ is the melt fraction and τ is the time (e.g., Turcotte and Schubert 2002). Melt fraction is assumed to depend only on temperature such that

$$X = F(T)$$

Equation 2

where F is a function derived from a simple three-component phase diagram based on a Hawaiian olivine tholeiite basalt (Sample 14, Yoder and Tilley 1962) with three components; the chemical analysis was recalculated as a CIPW norm (Cox et al. 1979) and the components were re-normalised to give olivine, clinopyroxene and plagioclase. The melt fractions corresponding to temperatures in the range 0 to 1320°C were calculated using the simulated phase equilibria model of Witham (2008). The simple three-phase system was used to test the model's performance when compared with analytical solutions, and to

explore the effects of different parameters. F (Equation 2) is generally determined from experimental studies. Here, it is approximated by a series of linear trends.

The far-field geotherm $T(z)$ is assumed to satisfy the boundary conditions

$$T \rightarrow \frac{Q_0}{K} z - \frac{A}{2K} z^2 \text{ as } x \rightarrow \pm \infty$$

Equation 3

where the surface temperature is taken to be zero. This equation is valid for all values of z .

The initial condition for a single injection is

$$T = T_m, \quad |x| < \omega; \quad T = \frac{Q_0}{K} z - \frac{A}{2K} z^2, \quad |x| > \omega \quad \text{at } \tau = 0$$

Equation 4

for $z_0 \leq z \leq z_1$, where z_0 and z_1 define the upper and lower surfaces of the modelled region of the crust (Figure 2) and whose temperature satisfies Equation (3) such that

$$T = \frac{Q_0}{K} z_0 \text{ at } z = z_0 \text{ and } T = \frac{Q_0}{K} z_1 \text{ at } z = z_1, \quad T_m \text{ is the magma injection temperature at}$$

time $\tau = 0$ and 2ω is the dyke width. Above and below the intruded region ($z < z_0$ and $z > z_1$), the thermal evolution of the crust is governed by the geotherm (Equation 3). Solutions of Equations (1) – (4) are required to determine how the temperature and melt fraction evolve as functions of x , z , and τ . Numerical solutions of Equations (1) – (4) were determined using an explicit finite difference method. A full description of the finite difference method is included as an appendix.

The heat-flow equation (Equation 1) was discretised using forward difference approximations in τ and a central difference approximation in x . The solution was computed forwards in time by incrementing the timestep (k) through integer values, starting with $k = 0$ where T and X are determined by the initial temperature profile (Equation 6). Due to the symmetrical nature of the solution about $x = 0$, the computational domain was restricted to

positive x values and a symmetry condition applied to the left hand edge of the domain. Successive intrusions of basalt at a constant injection rate were modelled numerically by displacing previously computed values of temperature rightwards (mimicking advection) by the half-dyke width at each new injection time and inserting the new intrusion of the same dyke width and temperature T_m in the space vacated. The advection of heat due to ductile stretching of the crust is not considered in our models since it will be negligible over the time-scales we model intrusions. Brittle deformation by faulting has also not been accounted for in the model. The injection frequency ψ was defined as the ratio of the magmatic extension rate S to the dyke thickness 2ω so that $S = 2\omega\psi$.

3. Specific Model Parameterisation for Ethiopia

The tectonically active East African Rift (EAR) and southern Red Sea Rift (RSR) in Ethiopia provide an excellent opportunity to source realistic input parameters for our thermal model (Figure 1). The starting composition was established using the lava from a 2007 fissure eruption in Afar (sample A2, Ferguson et al. 2010), with a water content of 0.4 wt% assumed at all depths. The series of linear fits used for the temperature-melt fraction relationship were determined using the MELTS (Ghiorso and Sack 1995, Asimow and Ghiorso 1998) and Rhyolite-MELTS (Gualda et al. 2012) thermodynamic modelling programs. The composition of the injected material and the intruded crust are assumed to be the same. Because the injected material mainly cools and the host rock predominantly slowly increases in temperature, the temperature-melt fraction relationship of the host material is not important and will not affect the temperatures produced (Daniels, 2012). The solidus temperature was based on previously published model temperatures (Annen and Sparks 2002).

The temperature-melt fraction relationship was calculated for four different pressures corresponding to different depths in the crust: $z = 5, 10, 15$ and 20 km (Figure 3). It has

been inferred from wide-angle seismic (Maguire et al., 2006), gravity (Cornwell et al., 2006) and electrical resistivity (Desissa et al., 2013) study in Ethiopia that gabbroic intrusions occur in this depth range in the upper crust beneath Quaternary-Recent zones of magmatic extension. Partial melt is also known to reside at these depths, as revealed by magnetotelluric analysis of the subsurface (Whaler and Hautot, 2006). The lithostatic pressures and corresponding depths (calculated using ρgh with $\rho = 2800 \text{ kg/m}^3$, Annen and Sparks 2002), along with all of the crystallisation points, are in Table 1. Values of the physical parameters assumed are summarised in Table 2. A dyke thickness of 15 m allowed different extension rates S to be achieved by varying the dyke injection frequency ψ . Previous models that varied dyke thickness and injection frequency whilst fixing extension rate have shown that thinner, more frequently intruded dykes increase the crustal temperature more quickly than thicker, less frequently intruded dykes, but the effect is insignificant compared with other parameters such as the extension rate (Daniels, 2012). It is for this reason that only one dyke thickness is chosen. Injection temperatures (T_m) in the range 1240-1320°C were studied.

4. Results

Two-dimensional model runs with $x_0 = 0$, $x_1 = 10 \text{ km}$, $z_0 = 0$, $z_1 = 10 \text{ km}$, $\Delta x = \Delta z = 5 \text{ m}$ and dyke width = 15 m were conducted for extension rates of 5, 10, 15 and 20 mm/yr and for a duration of 200 ka. In these models, the injected dyke extended over the depth of the computational array. Figure 4 shows the output of these two-dimensional models and the brittle-ductile transition (black line) and solidus (red line) isotherms migrating across the computational domain. Loss of heat at the top and bottom of the domain can be seen to affect the temperatures.

As detailed in the supplementary material, the model was tested successfully against independent analytical solutions. Moreover, except at the top and bottom of the model, this

203 2D numerical model can be approximated by a 1D model where the temperature profile
204 depends only on the horizontal distance x at a given, constant depth z : both 1D and 2D
205 numerical models yield similar solutions (see the supplementary material for details).
206 However, at the top and bottom of the modelled region of the crust, the thermal boundary
207 conditions influence the solution there immediately and eventually affect the solution
208 throughout the model space. But, if these upper and lower boundaries (z_0 and z_1) are
209 sufficiently far apart, the 1D model yields a very good approximation for the model interior,
210 thus reducing computational time considerably.

211 At the top of the 2D model, the boundary effect is analogous to the surface cooling of the
212 system (see the supplementary materials for details). The amount of the modelled crust
213 affected after time τ can be approximated using $\ell^2 \sim \kappa\tau$ such that after 1 Ma, the top 4 km of
214 the crust will have experienced surface cooling, increasing to 7 km after 3 Ma. For depths
215 >5 km, the 1D heat flow equation is thus appropriate for the study of the thermal structure of
216 continental crust during extension by dyke intrusion over a time period of a couple of Ma.

217 The 1D numerical model was run using the parameters in Table 2 for extension rates of 3, 5,
218 10, 20, and 25 mm/yr, for a horizontal range of $x_0 = 0$ to $x_1 = 30$ km and at depths (z) of 5,
219 10, 15, and 20 km. These extension rates were designed to encompass the ~ 6 mm/yr
220 extending MER, and the ~ 16.4 mm/yr extending RSR in Afar. Each model was run for 5 Ma,
221 with temperature monitored as a function of distance from dyke injection point. Particular
222 attention was paid to the solidus temperature and brittle-ductile transition (600°C) isotherms.
223 Magmatic extension rate and the time taken to reach the solidus temperature or the brittle-
224 ductile 600°C isotherm at the injection position ($x=0$) display an inverse power law
225 relationship (S is proportional to $\frac{1}{\sqrt{\tau}}$; Figures 5 and 6). Thus, magmatic extension rate is
226 approximately proportional to $\frac{1}{\sqrt{\tau}}$, independent of injection temperatures (Figure 5). Injection
227 temperature is thus secondary to extension rate in governing the rate of temperature
228 increase.

The distance (x) from the dyke injection and the time taken to reach a given isotherm correlate linearly for all extension rates (S) (Figure 7 A). The linear trend indicates that the magmatic extension rate is dominant at distances close to the dyke injection location. Figure 7 B shows modelled isotherm positions as a function of distance from the dyke injection point; also shown are isotherm positions determined from extension rate alone (effects of conduction are close to negligible). Extension rate is a good proxy for isotherm migration rate in the near field, but with increasing distance from the injection point, conduction becomes an increasingly important additional effect.

When the time is plotted as a function of extension rate (Figure 6), the results are comparable with the results of Michaut and Jaupart (2006) who found that the critical temperature in their numerical models (t_c) was inversely proportional to injection rate squared (Q^2). The constant that multiplies the injection rate in Michaut and Jaupart (2006) and the extension rate in each of the relationships in Figure 6 is dependent on the parameters used in the modelling (Table 2) and therefore is different for each case. However, in both this study and in Michaut and Jaupart (2006), the time taken to reach a particular temperature is inversely proportional to the square of the extension rate. The timescales for the build up of temperature calculated for different magmatic extension rates are quite varied. Calculations show that it will take significantly longer for the ambient temperature to build up at slower extension rates: an extension rate three times faster will decrease this time by an order of magnitude (Figure 5).

5. Discussion

5.1. Overview

It is now well established that dyke intrusion achieves a significant proportion of extension during continental rifting (e.g., Maguire et al., 2006; Thybo and Nielsen, 2009; White et al., 2008), yet relatively little attention has been paid in the rifting community to the effects this

has on the thermal evolution (and by inference the strength) of the continental crust during breakup. Previous studies have demonstrated that appreciable crustal heating occurs due to repeated magma intrusion in arc settings (e.g. Annen et al. 2006, Solano et al. 2012), and a similar thermal modelling approach has been followed in this study of continental rifting.

This study demonstrates that the thermal structure of the crust is controlled by several factors: intrusion depth, injection temperature, and magmatic extension rate. Of these, magmatic extension rate exerts first order control on crustal thermal structure (Figures 5, 6 and 7). The rate of transfer of heat laterally away from the zone of dyke intrusion can be approximated in the near-field by the magmatic extension rate, but at greater distances (>3-4 km), cooling by conduction becomes an important factor (Figure 7).

The location of the injection relative to the previous injection is also likely play a role in the timescale of the build-up of heat in the crust. Here, each successive injection has intruded through the centre of the previous injection. This may have had the effect of insulating each hot injection from the cooler crust to either side and therefore indicate that the timescales calculated represent minimum estimates. Additionally, the advection of heat due to ductile stretching of the crust has not been accounted for in the model. At slow extension rates relevant for continental rift zones, this effect is negligible compared to the marked and rapid heating caused by intrusion. At faster rates of extension observed at mid-ocean ridges, but rare for continental rifts, the advection of heat is likely more important.

Observations of seismicity worldwide indicate strongly that earthquake depths are fundamentally limited by the brittle-ductile transition in continental crust and commonly the 600°C isotherm is used to mark this transition in typical crust (e.g., Maggi et al., 2000a,b; Jackson, 2002). A 10-20 km wide region of the crust would be expected to heat to above 600°C in <1 Ma, even at relatively slow extension rates of ~10 mm/yr (Figure 7). At slower rates, heating to 600°C will take much longer (e.g., 6.3 Ma for a 20 km-wide region at 3 mm/yr).

5.2. Implications for the thermal development of the MER

The MER is the northern-most sector of the EAR and displays several stages of rift sector development along strike. Embryonic continental rifting in the southern MER is dominated by border faulting while in the northern MER, rifting is more evolved and axial magma intrusion contributes significantly to Nubia-Somalia separation (e.g., Hayward and Ebinger 1996; Kogan et al., 2012). The northern MER has also undergone considerable development over time: initial rifting during Miocene times was characterised by upper-crustal extension accommodated by the large-offset border faults that define the rift valley flanks today (e.g., Wolfenden et al., 2005). Since Quaternary times however, faulting and volcanism have localized to the 20-30 km wide WFB axial zone. Aligned Quaternary-Recent monogenetic basaltic cones and resultant lava flows cut by the most active faults within the MER, coupled with geodetic evidence that ~80% of Nubia-Somalia plate separation is presently accommodated within the WFB (Bilham et al., 1999), was cited by Ebinger and Casey (2001) as evidence that a significant proportion of extension in the MER is achieved by episodic magma intrusion. More recent studies of GPS measurements acquired over the last two decades confirm the MER is currently opening at 5-6 mm/yr in an ESE-WNW direction (Kogan et al., 2012). The seismic moment release in the MER since 1960 is around half that expected from the plate separation velocities, which suggests 50% of the extension is accommodated by aseismic processes such as magma intrusion (Hofstetter and Beyth, 2003).

The 2001-2003 Ethiopia Afar Geoscientific Lithospheric Experiment (see Bastow et al., 2011 for a review) has facilitated the development of high-resolution sub-surface geophysical models of the MER. Wide-angle active-source, passive-seismic, and gravity studies of crustal structure have shown that zones of Quaternary-Recent magmatism in the WFB are underlain by anomalously high P-wavespeed and high-density material compared to surrounding native continental crust (e.g., Keranen et al., 2004; Mackenzie et al., 2005; Daly et al., 2008; Cornwell et al., 2006; Maguire et al., 2006; Tiberi et al., 2005). These are

308 interpreted as zones of localised gabbroic intrusions that extend from the aligned
309 monogenetic cone fields along the rift axis surface to the base of the crust at 30-35 km depth
310 (e.g., Keranen et al., 2004; Mackenzie et al., 2005). While the total volume of new intruded
311 material beneath the axis is debated, the marked reduction in seismic velocities in the upper
312 ~8 km of the crust suggests intrusion contributes a lower proportion of extension at these
313 shallow depths compared to elsewhere in the crust (Keranen et al., 2004).

314 The thermal models developed in this study show that ~6 mm/yr extension in the MER
315 should, if achieved 100% by magma intrusion, by now have heated the crust to
316 temperatures in excess of 600°C (Figures 5 and 7). Observations of seismicity in the MER
317 render this hypothesis implausible, however. Variations in seismicity along the WFB instead
318 demonstrate along-axis variability in the thermal state of the crust. The Boset segment
319 (Figure 1) is the most magmatically active portion of the MER (e.g. Abebe et al., 2007) and
320 accordingly exhibits the least seismicity and shallowest brittle-ductile transition at 6-9 km
321 depth (Beutel et al., 2010). Crustal tomographic studies indicate the highest P-wavespeed
322 anomalies anywhere along the MER occur in the Boset segment, with the implication that
323 the crust here contains a higher proportion of new igneous material than elsewhere along
324 the rift (e.g. Keranen et al., 2004; Maguire et al., 2006). In other areas of the MER, with
325 lower amplitude high P-wavespeed anomalies, seismicity is evident to depths of 15-18 km,
326 indicating higher crustal strength and lower temperatures (Beutel et al., 2010).

327 If only 50% of the 6 mm/yr extension in the MER has been achieved by dyke intrusion
328 beneath the WFB, the thermal models presented in this study would predict a significantly
329 smaller degree of heating and weakening. Extrapolating from Figure 7, a zone 20 km wide
330 would heat to the brittle-ductile transition at all depths only after about 6 Ma. This is a longer
331 period of time than the WFB has existed within the MER: earlier extension was confined to
332 the large-offset border faults (Wolfenden et al., 2005). The depth extent of seismicity and
333 variations in P-wave speeds beneath the magmatic segment along the axis of the MER
334 when interpreted in light of our thermal modelling supports the interpretation that the crust

beneath the WFB is not 100% new mafic material. Rather it is a zone of heavily intruded continental crust. Mechanical extension (faulting and stretching) thus remains an important mechanism of strain accumulation between Nubia and Somalia.

5.3 Implications for the development of continent-ocean transition

In contrast to the relatively young magmatic phase of extension observed in the MER, Afar has experienced magma assisted rifting since the Miocene (Wolfenden et al. 2005). Our models predict that given the higher extension rate (~16 mm/yr) and longer period of time elapsed since the onset of magma intrusion, crustal temperatures should be too high for brittle deformation to occur; the crust should thus now be able to deform in a ductile manner (stretching). However, most of sub-aerial Afar has generally thick crust (Makris and Ginzburg, 1987; Hammond et al., 2011), and is still seismically active (Ayele et al., 2007a,b; Keir et al., 2011a,b; Ebinger et al., 2013) indicating that magma intrusion has not thermally weakened the plate as much as suggested by the model. A simple explanation for this is that the Arabia-Nubia plate boundary has shifted north-eastward several times in response to triple junction development in Afar. During earlier phases of magma-assisted rifting in Miocene times, strain was accommodated in magmatic segments located proximal to the western southern Red Sea border fault on the western margin of Afar (e.g. Wolfenden et al, 2005). Since then, strain has localised progressively north-eastward to form the current configuration of axial volcanic segments (e.g. Dabbahu and Harraro segments) and sometimes amagmatic grabens (e.g. Tendaho; Dobi and Hanle graben: Tesfaye et al., 2003). Consequently, magma intrusion is unlikely to have been localised for long enough in any given location for sufficient crustal heating to occur. As a result, extension by dyke intrusion remains the optimal straining mechanism (e.g., Buck, 2006), with plate strength likely still too high to permit significant ductile stretching localised around the intrusion zone.

Our thermal models show that only when dyke intrusion is focused to one magmatic segment for a protracted period of time would aseismic ductile deformation be expected to

commence (Figures 5 and 7). One region where this transition may be underway is the sub-aerial but below sea-level Danakil depression in northernmost Afar. Here rapid basin subsidence since ~5 Ma indicated by 3-5 km accumulations of Pliocene-Recent sediments, combined with a pulse of Quaternary-Recent fissural basaltic volcanism, were interpreted by Bastow and Keir (2011) as evidence for a late stage of plate stretching and an increase in decompression melting in the mantle. The Bastow and Keir (2011) study lacked constraint on the mechanism responsible for the shift from extension by magma intrusion to extension by ductile stretching, but noted that late-stage subsidence and volcanism is a common feature of the geological record at magmatic rifted margins globally. The thermal models presented in this study show that at the ~10 mm/yr extension rates observed in the Danakil depression (McClusky et al, 2010), a 20 km wide zone will be sufficiently heated at 5 km depth after about 1 Ma of extension by magma intrusion to deform in a ductile fashion (Figure 7). However, in the Danakil depression where plate stretching has commenced, heat advection is likely to be a considerable additional component. A hotter and weaker plate in the Danakil depression is supported by earthquakes restricted to the upper ~5 km of the crust (e.g., Craig et al., 2011; Nobile et al., 2012), and ~5 km effective elastic plate thickness derived from gravity-topography coherence studies of plate strength (Ebinger and Hayward, 1996; Perez-Gussinye et al., 2009). When synthesized in light of a priori geoscientific constraints from the Danakil region, our thermal models thus indicate that a late-stage of localised plate stretching, with an associated pulse of decompression melting, can readily characterise the final stages of continent to ocean transition.

6 Conclusions

We have developed a numerical solution to the heat-flow equation to quantify the effects of dyke intrusion on the thermal structure of the crust during rifting, and on the timescales of the heating at varying magmatic extension rates. The rate of extension by intrusion is shown

to exert first order control on crustal thermal structure, and when extension is achieved entirely by dyke intrusion, the crust is expected to heat considerably on time-scales of less than 1 Ma.

We benchmarked our thermal models against recently developed constraints on crustal structure and dyke intrusion episodes in Ethiopia. For the MER, our model predicts brittle deformation at the ultra-slow extension rates of ~6 mm/yr will cease after only 300 ka of entirely magmatic extension localised to the rift axis. Our thermal calculations, corroborated by observations of seismic moment release, depth extent of seismicity, and P-wave speeds, point instead to a rifting model by which only ~50% of the extension is accommodated by magma intrusion. In the Danakil depression of northernmost Afar in contrast, a combination of faster extension rates of ~10 mm/yr and longer history of magma intrusion has likely resulted in sufficient heating and weakening of the plate to induce a late stage phase of localised ductile stretching near the intruded zone. Our results demonstrate the significant impact of dyke intrusion on the rheology of continental crust during rifting. The challenge now is to understand better how dyke intrusion affected plate strength during the development of magmatic margins worldwide.

Acknowledgements

KAD would like to thank G. P. Daniels, P. G. Daniels and F. Witham for early assistance with the numerical coding and helpful discussions thereafter. C. Annen, J. D. Blundy, G. A. Jones and K. A. Whaler are also thanked for constructive comments and suggestions. The authors are grateful to three anonymous reviewers whose comments have strengthened and improved the manuscript. KAD was supported by a NERC Consortium Grant. RSJS is co-supported by a grant from the European Research Council. IDB is funded by the Leverhulme trust.

604 rifts. Red segments show the Quaternary-Recent subaerial rift axes. DD: Danakil
605 Depression. TGD: Tendaho-Goba'ad Discontinuity. MS: magmatic segments. DG: Dobi
606 Graben. HG: Hanli Graben. Dashed red lines are sea-floor spreading centres in the Red
607 Sea and Gulf of Aden. Top left inset: topography of NE Africa and Arabia. Arrows show
608 plate motions relative to a fixed Nubian plate. Red lines are plate boundaries.

609 Figure 2: A schematic diagram showing the set-up of the model relative to the overlying rift
610 topography, and the dimensions and position of the computational domain within the crust.

611 Figure 3: Temperature versus melt fraction for 4 different pressures, calculated using
612 MELTS (Ghiorso and Sack, 1995; Asimow and Ghiorso, 1998), Rhyolite-MELTS (Gualda et
613 al., 2012) and experimental estimates of the water-saturated granite solidus (Stern and
614 Wyllie, 1973; Annen and Sparks, 2002). Small differences in the melt fraction-temperature
615 relationship will have a minimal effect on the results.

616 Figure 4: Outputs from two-dimensional model runs with $z_0 = 0$ and $z_1 = 10\text{km}$, and $\tau = 20$
617 ka, 100ka and 200 ka. Above: extension rate $S = 5\text{ mm/yr}$. Below: $S = 20\text{ mm/yr}$. The brittle-
618 ductile transition (black line) and solidus (red line) isotherms are highlighted.

619 Figure 5: Extension rate versus the time, expressed in ka, taken to reach the solidus and
620 600°C isotherm temperatures at 5 km depth at the injection position. The extension rates of
621 the MER ($\sim 6\text{ mm/yr}$) and RSR ($15 - 20\text{ mm/yr}$) are highlighted. The injection temperatures
622 are in the range $T_m = 1220$ to 1320°C .

623 Figure 6: Time taken to reach the 600°C isotherm temperature as a function of extension
624 rate.

Figure 7: A) Time taken to reach the solidus temperatures as a function of the distance away from the dyke injection point, at 5 km depth. B) The position of the 600°C isotherm (solid lines and unfilled dots) due to the model (lines) and the extension rate alone (dots). The component of the extension rate alone is calculated using the time taken to reach the 600°C isotherm at distance $x = 0$ as the starting point, and then migrating the isotherm away from the starting point at the magmatic extension rate. Extension rates of 5 mm/yr (grey solid lines and unfilled dots) and 20 mm/yr (black solid lines and unfilled dots) are shown. The arrows show the components of extension alone (black arrow) versus the cooling due to conduction (grey arrow). The first arrow is much longer than the second one, illustrating that the time taken to reach the isotherm is primarily controlled by the extension rate; accounting for heat loss by conduction increases this time but this effect appears to be secondary.

Table captions

Table 1: Temperatures (T) in °C, and corresponding melt fractions (X) for four different pressures: 137.34 MPa (5 km depth); 274.68 MPa (10 km depth); 412.02 MPa (15 km depth); and 549.36 MPa (20 km depth). Subscripts l, e and s correspond to the liquidus, eutectic and solidus temperatures respectively; c and c2 are arbitrary points on the X-T diagram chosen to give the best fit to the data.

Supplementary Material

649 Practical Implementation of the Model

650 Numerical solutions of Equations (1) – (4) were determined using an explicit finite difference
 651 method. The heat-flow equation (Equation 1) was discretised using forward difference
 652 approximations in τ and a central difference approximation in x to give

$$\begin{aligned} \frac{T_{(i,j,k+1)} - T_{(i,j,k)}}{\Delta\tau} + C \frac{X_{(i,j,k+1)} - X_{(i,j,k)}}{\Delta\tau} \\ = \kappa \left(\frac{T_{(i+1,j,k)} - 2T_{(i,j,k)} + T_{(i-1,j,k)}}{(\Delta x)^2} \right. \\ \left. + \frac{T_{(i,j+1,k)} - 2T_{(i,j,k)} + T_{(i,j-1,k)}}{(\Delta z)^2} \right) \end{aligned}$$

654 **Equation A1**

655 where $C = L / C_p$. Here $T_{(i,j,k)}$ and $X_{(i,j,k)}$ are numerical approximations to T and X at location x
 656 $= i \Delta x$, $z = z_0 + j \Delta z$ and time $\tau = k \Delta \tau$ where Δx , Δz and $\Delta \tau$ are the step lengths in x , z and
 657 τ respectively. The modelled region of the crust is taken as $-x_\infty \leq x \leq x_\infty$, $z_0 \leq z \leq z_1$ where i
 658 ranges from $-N$ to N with $x_\infty = N \Delta x$; j ranges from 0 to M with $z_1 - z_0 = M \Delta z$. N and M
 659 are sufficiently large to accommodate the outer behaviour. Equation (5) can then be written
 660 as

$$T_{(i,j,k+1)} + C X_{(i,j,k+1)} = R_{(i,j,k)}$$

662 **Equation A2**

663 where

$$\begin{aligned} R_{(i,j,k)} = T_{(i,j,k)} + C X_{(i,j,k)} + A (T_{(i+1,j,k)} - 2T_{(i,j,k)} + T_{(i-1,j,k)}) + B (T_{(i,j+1,k)} \\ - 2T_{(i,j,k)} + T_{(i,j-1,k)}) \end{aligned}$$

665 **Equation A3**

666 and $A = \frac{\kappa \Delta \tau}{(\Delta x)^2}$, $B = \frac{\kappa \Delta \tau}{(\Delta z)^2}$ and must be solved in conjunction with the X - T relation

667 (Equation 2) in discretised form to find the solution values $T_{(i,j,k+1)}$ and $X_{(i,j,k+1)}$ at the new time-

step and each internal grid point (i,j) . With F of piecewise linear form, $T_{(i,j,k+1)}$ and $X_{(i,j,k+1)}$ can be found exactly, depending on which linear section of F is relevant for any given value of $R_{(i,j,k)}$. Since Equation (8) describes a straight line of gradient $-1/C$, its intersection with Equation (2) is determined by the size of $R_{(i,j,k)}$ relative to the value of R associated with each crystallisation point. The new temperature and melt fraction are thus calculated as

$$T_{(i,j,k+1)} = \frac{R_{(i,j,k)} - C q}{1 + mC}, \quad X_{(i,j,k+1)} = m T_{(i,j,k+1)} + q$$

Equation A4

where m and q are defined by the gradients and intercepts respectively, of the linear sections of F .

Values of T and X on the boundaries of the modelled region of the crust are given by the boundary conditions (Equations 3, 4 and 5) applied at $x = \pm x_\infty$. Because the solutions for T and X are generally symmetric about $x = 0$, the computational domain can be halved by applying the boundary condition $\frac{\delta T}{\delta x} = 0$, at $x = 0$ and restricting attention to the region $0 \leq x \leq x_\infty$, $z_0 \leq z \leq z_f$. Numerically, this condition can be applied using a quadratic interpolation of T near $x = 0$, leading to the result that

$$T_{(0,k+1)} = \frac{1}{3} (4 T_{(1,k+1)} - T_{(2,k+1)}).$$

Equation A5

Once the values of $T_{(i,j,k+1)}$ are determined, Equation (9) can be used to determine T at the dyke injection point ($x = 0$).

Analytical Solutions

Various analytical results can be obtained for the 1D heat-flow equation, which can then be used as approximations for the 2D heat-flow equation (Equation 1). The excess heat content, Q , is independent of time and can be used to calculate the temperature at any given

time. This is because the excess heat content over all space $-\infty < x < \infty$ at a general time τ must be equal to that of the dyke at $\tau = 0$. At large time τ , the temperature can be found explicitly via $x \sim 2 (\kappa \tau)^{1/2}$ (Turcotte and Schubert, 2002)

It is also possible to obtain an exact analytical solution to Equations (1) - (4) if the effect of latent heat is neglected ($L=0$) (see, Carslaw and Jaeger 1950), which gives the peak temperature at the centre of the domain, $x=0$, in terms of error functions (see Daniels 2012 for full details).

Model Validation

1D Model

The physical parameters were assigned values according to Table A.1. Initially, latent heat effects were ignored. This was done to test the model against the analytical solution that exists without L (Carslaw and Jaeger, 1950). Assuming the upper and lower surfaces (z_0 and z_1 respectively) are sufficiently far apart, 1D analytical results are applicable to the 2D case for a fixed value of z . The decay over time of the dyke's thermal anomaly relative to the ambient temperature gives an analytical solution at large time τ (Equation 4-170, Turcotte and Schubert 2002). An exact solution is obtained if the effect of latent heat is neglected ($L=0$, see, Carslaw and Jaeger 1950).

Figure A.1 A) shows the numerical solution for the peak temperature at the centre of the dyke, $x = 0$, as a function of time, along with the corresponding exact solution. There is excellent agreement, with the error reaching a maximum, yet small, value at small time where the numerical method has difficulty in accurately resolving the large change in temperature at the edge of the dyke (Figure A.1 B). Figure A.1 C) shows the heat content integral, per unit area of the dyke-country rock interface, plotted as a function of time. For these parameters (Table 4) it should have the constant value $Q / \rho = 9.768 \times 10^6 \text{ J kg}^{-1} \text{ m}^{-1}$

and this is accurately reproduced for times τ of up to about 1.5×10^9 s. For larger times the outer boundaries of the computational domain begin to influence the solution because the diffusion scale $x \sim 2 (\kappa \tau)^{1/2}$ becomes comparable with the size of the domain.

The effect of latent heat is now considered. The parameter values used are the same as those in Table 4 with latent heat $L = 4 \times 10^5$ J kg⁻¹ (Turcotte and Schubert 2002). Figures A.2 A) and B) show the temperature profile obtained numerically at time $\tau = 3.11 \times 10^9$ s for a dyke width of 5 m with $\Delta\tau = 3600$ s, $\Delta x = 1$ m and $x_\infty = 200$ m, in excellent agreement with the analytical solutions. Figures A.2 C) and D) show the temperature at the centreline $x = 0$ as a function of time. A comparison is made with the analytical result where $Q / \rho = 1.1768 \times 10^7$ J kg⁻¹ m⁻¹. Figure A.2 E) and F) show that the numerical solution is consistent except for very small times where inaccuracy is introduced through the rapid change in temperature at the edge of the dyke.

Also, the 1D numerical model is tested against the analytical solution for the decay over time of the dyke thermal anomaly relative to the ambient temperature. At large time, the temperature at the centre of the numerical domain should decay as the square root of time:

$$T(0, \tau) = \frac{Q}{2\rho C_p \sqrt{(\pi\kappa)}} \tau^{-1/2} \quad (\text{Equation 4.170, Turcotte and Schubert, 2002})$$

Figure A.3 confirms that this behaviour is accurately reproduced by the numerical solution.

Finally, tests were carried out to investigate the effect of step lengths Δx and $\Delta\tau$ on the numerical solution. Figure A.4 A shows results obtained for the parameter values in Table 4, $L = 4 \times 10^5$ J kg⁻¹ and a dyke width of 30 m. Computations were performed with $x_\infty = 400$ m, $\Delta\tau = 3600$ s and three different spatial steps $\Delta x = 2$ m, 6 m and 10 m. These confirm the gradual loss of accuracy with increasing Δx . Figure A.4 B shows results obtained for the same physical parameters but with a dyke width of 3 m. Here the computations were carried out with $x_\infty = 100$ m, $\Delta x = 1$ m and two different time steps $\Delta\tau = 5000$ s and 10000 s. The reduction in accuracy by using the larger time step is not significant and justifies the use of a

larger time step in subsequent calculations, provided the condition for numerical stability is maintained.

One-dimensional versus two-dimensional models

The boundary effect at the top and bottom of the 2D model gradually has an effect on larger and larger areas of the interior solution with increasing time. At the top of the computational domain, this is analogous to the surface cooling of the system and allows an appreciation of the likely effect of surface cooling on the system after any specified time (Figure A.5). Except at the top and bottom of the two-dimensional model, the one and two-dimensional models yield same solutions. This is shown in Figure A.6 where the two-dimensional solution at different depths (z) has been compared with a one-dimensional model solution for that depth. The interior solutions to the 2D numerical model are comparable with the 1D model results.

Figure A.1: Comparison of the 1D numerical solution for $L=0$ J/kg, $T_m = 1320^\circ\text{C}$ and $\omega = 2.5$ m with the analytical solution for the peak temperature over time. A) The numerical and analytical peak temperatures. B) The difference between the analytically and numerically calculated temperature values. The difference is calculated as the analytical temperature minus the numerical temperature. C) Heat content integral as a function of time for the computation of A) and B). D) The percentage difference between the calculated heat content integral and the expected analytical value.

Figure A.2: A) 1D numerical solution for $L = 4 \times 10^5$ J/kg, $T_m = 1320^\circ\text{C}$ and $\omega = 2.5$ m at time $= 3.11 \times 10^9$ s (100 years) using $\Delta\tau = 3600$ s and $\Delta x = 1$ m; the large-time analytical solution is also shown. B) The difference between the analytical and numerical solutions. C) 1D numerical solution for the peak temperature at the centreline $x = 0$ as a function of time for

766 the computation of A) and B); the large-time analytical solution is also shown. D) The
 767 difference between the analytical and numerical solutions. E) Heat content (Q) as a function
 768 of time for the computation of A) and B). F) The percentage difference between the
 769 calculated heat content integral and the expected analytical value.

770 Figure A.3: The ratio of the 1D numerical solution to the exact analytical solution for the
 771 temperature at the centre of the dyke $\frac{\frac{1}{2}T(0,\tau)x}{2\rho Cp(\pi\kappa)^{\frac{1}{2}}/Q}$, as a function of time for the
 772 computation of Figure A.2. Close proximity to the analytical solution is achieved almost
 773 immediately with the exact analytical solution reached in 30.95 years or 315 time steps.

774 Figure A.4: A) Difference between the analytical and numerical solutions for $L = 4 \times 10^5$ J/kg,
 775 $T_m = 1320^\circ\text{C}$ and $\omega = 15$ m at time $\tau = 3.11 \times 10^9$ s (100 years) using $\Delta\tau = 3600$ s and $\Delta x = 2$
 776 m, 6 m, and 10 m. B) Difference between the analytical and numerical solutions for $L = 4 \times$
 777 10^5 J/kg, $T_m = 1320^\circ\text{C}$ and $\omega = 1.5$ m at time $\tau = 10^8$ s (1157 days / ~3.2 years) using $\Delta x =$
 778 1 m with $\Delta\tau = 5000$ s and 10000 s.

779 Figure A.5: Temperature contours for the numerical computations of the 2D heat-flow
 780 equation with $L = 4 \times 10^5$ J/kg, $T_m = 1320^\circ\text{C}$, $z_0 = 1000$ m, $z_1 = 5000$ m, $Q_0/K = 0.03^\circ\text{C/m}$ and
 781 $\omega = 7.5$ m, obtained using $x_\infty = 4000$ m, $\Delta x = \Delta z = 5$ m, $\Delta\tau = 3.11 \times 10^6$ s. The temperature
 782 shown is that recorded at the time step immediately prior to the next injection at time = 2.49
 783 $\times 10^{12}$ s (80 ka) for extension rate $S = 25$ mm/yr.

784 Figure A.6: Numerical solutions for the 2D model with $L = 4 \times 10^5$ J/kg, $T_m = 1320^\circ\text{C}$, $z_0 =$
 785 1000 m, $z_1 = 5000$ m, $Q_0/K = 0.03^\circ\text{C/m}$ and $\omega = 7.5$ m with an extension rate $S = 25$ mm/yr;
 786 also the equivalent 1D calculations at depths z given by A) 1500 m, B) 2750 m, C) 3000 m,
 787 D) 3250 m, E) 4500 m obtained using $z(Q_0/K)$. The computations were performed with $x_\infty =$
 788 4000 m, $\Delta x = \Delta z = 5$ m, $\Delta\tau = 3.11 \times 10^6$ s and show the temperature recorded immediately
 789 prior to the next injection at time = 6.22×10^{11} s (~20 ka).

793 solution. ^aAnnen and Sparks (2002); Bohrson and Spera (2001); Laube and Springer (1998);
794 Rivers and Carmichael (1987). ^bUsing $\kappa = K / \rho C_p$, with $K = 1.15 \text{ W/m/K}$ (Spera, 2000), $\rho =$
795 $2.8 \times 10^3 \text{ kg/m}^3$ (Annen and Sparks, 2002) and $C_p = 1.48 \times 10^3 \text{ J/kg}$ (Annen and Sparks,
796 2002)

Highlights

- A numerical solution to the heat-flow equation is developed
- Dyking has a significant thermal effect on crust rheology during rifting
- Extension rate exerts first-order control on crustal thermal structure during rifting
- The crust is expected to heat considerably on time-scales of less than 1 Ma
- In the MER dyking has localised for insufficient time for significant crustal heating
